Dung beetles and their role in the nature
Adam Byk, Jacek Piętka

Summary:
Scarabaeoid beetles (Scarabaeoidea) inhabit all zoogeographical regions of the world. However, coprophagy as the type of nutritional specialization dominates among the scarabaeoid beetles. The number of dung beetles (coprophagous Scarabaeoidea) is estimated at about 7,000 species. There are about 460 of dung beetles species in Europe, and about 90 of dung beetles species in Poland. Dung beetles can be endocoprids (dwellers), paracoprids (tunnelers) or telecoprids (rollers). Endocopric species lay eggs directly into the dung, paracropic species dig earth tunnels of various lengths ending with brooding chambers beneath the dung, and telecopric species separate a portion of dung and roll it into round balls which are then transported, sometimes far from the original source of the dung, to a place where the beetles dig tunnels ending with brooding chambers. Such a variety of methods of using faeces by dung beetles cause an accelerated circulation of nutrients, increased soil aeration, plant spreading, and a reduction in the number of parasites (flies and nematodes). Among dung beetles presently encountered in Poland there are endocopric and paracopric species.

Key words: Scarabaeidea, Scarabaeidae, Geotrupidae, dung beetles, scarab dung beetles, earth-boring dung beetles, animal faeces

Introduction
Insects are the most numerous group of animal species on Earth with their quantity estimated at around 1.5 million species. The largest group of the insects (over 400,000 species) belong to the order of beetles (Coleoptera). Scarabaeoidea is one of the superfamilies of the beetles, which inhabit all zoogeographical parts of the world. Most of them inhabit the tropical zone, and their number tends to rapidly decrease northwards (Tesaf, 1957).

The Scarabaeoidea superfamily is dominated by a group of species that feed on animal dung (coprophages). The recently found dung fossils indicate the existence of dung beetles (coprophagous Scarabaeoidea) in the age of the dinosaurs, even before the evolution of mammals (Chin and Gill, 1996). Currently, the number of dung beetles is estimated at 7,000 species (Hanski and Cambefort, 1991).

In Europe, the dung beetles include primarily the representatives of two families: earth-boring dung beetles – Geotrupidae (approximately 60 coprophagous species) and scarab dung beetles – Scarabaeidae (approximately 400 coprophagous species).

Farther and deeper
In Poland, the dung beetles fauna – formerly referred to by Hildt (1896) as “Domestic dung beetles” – represents approximately 90 species. However, the prevalence of several of these species is yet to be confirmed by new finds.

The systematic arrangement and nomenclature of the species have been adapted from the “Catalogue of Palearctic Coleoptera” (Löbl and Löbl, 2016).

Whatever it is that dung beetle buries and abandons the next day, is by no means lost. Nothing is lost in the balance of life, the whole of the inventory remains constant. A small pellet of manure buried by an insect will make the neighboring patch of grass turn delightfully green. The ram will come over and pluck the whole patch, and thus the better the roast a man expects of him will be. Thanks to the dung beetle industry, we get a perfect bite of meat.

Jean Henri Fabre

the top layer of the soil, directly underneath the dung. The Paracoprids dig tunnels of various lengths in the ground, underneath the faeces. The tunnels are terminated with hatching chambers. As regards the Telecoprids, upon earlier separation and formation of a piece of dung, they roll it away and dig their tunnels, terminated with hatching chambers, at considerable distances from the dung. The chambers are used for storing the transported portions of the dung (Fig. 1).

The dung beetles commonly found in Poland include the Endocoprid and Paracoprid species (Byk, 2011; Byk, 2012; Kamiński, Byk and Tykarski, 2015).

The Endocoprid grouping is represented by aphodiine dung beetles (Fig. 2). They are the dominant coprophagous beetles in northern Europe and play a significant role in disposing of dung, and thus in circulating the natural organic substances and providing nutrients to the flora (Fry and Lonsdale, 1991).

*Agrilinus ater* (De Geer, 1774) (Fig. 2A) feed on fresh dung inside which females lay eggs. The eggs are laid as early as on the second day after the exposure of fresh dung inside which females lay eggs. The eggs are located close to Minsk in Belarus. Imagines and larvae were found directly in horse dung (Frolov and Akhmedova, 2006).

The aphodiine dung beetles grouping observable in Poland also includes species applying a slightly different method of using dung (Fig. 3).

*Orodaliscus rotundangulus* (Reitter, 1900) (Fig. 3A) lives in the burrows of speckled ground squirrel – *Spermophilus suslicus* (Güldenstaedt, 1770), bobak marmot – *Marmota bobak* (Müller, 1776) (Byk and Bidas, 2011), which is not present in our country, and little ground squirrel – *Spermophilus pygmaeus* (Pallas, 1778) (Martynov, 2007). In Poland, this beetle is observed on extremely rare occasions, in the form of a single specimen, and is known to exist only on 5 sites located in the Lublin Upland. Strong populations of this species are found in the “Popówka” and “Suśle Wzgórza” reserves. The swarming of this species takes place during the last days of April or in the first half of May. The beetles leave the squirrels’ burrows during the afternoon or evening hours. From a nest chamber located at a depth of 60-150 cm and a tunnel (latrine) extending from it, the beetles leave the site via a short and slanted corridor (elbow) and then, they climb up the side-walls of the vertical corridors (wells). It is both, males and females that leave the burrows, and after that, they bury themselves underneath a moist soil, at a close distance to the exit holes (Byk and Bidas, 2011). The presence of this beetle species in traps filled with cattle dung bait indicates their coprophagous genus (Piasecki, 2013).

Contrary to the Endocoprids, the *Colobopterus erraticus* (Linnaeus, 1758) (Fig. 3B), which is quite popular in our country, has a different way of behaving. A female of this species digs 4-10 curved tunnels in the soil, directly underneath the dung, at a depth of 3-5 cm (10-11 cm on rare occasions). She always lays eggs one-by-one in a small-size cavity in the soil, most frequently in the lower part of the tunnel. It takes the beetle a few hours to fill the tunnel (or rather its lower part referred to as larder) and to create a sausage-like breeding lump (brood mass). The mass weighs between 0.6 and 4 grams. It is about 7 mm in diameter and from 1.5 to 3.5 cm in length. It takes approximately 10 days for the female to build a nest with 8 tunnels filled with nourishment for the offspring. The larvae feed on the dung collected by the female and, should their supplies run out, they move close to the dung located right above them. The metamorphose takes place in the soil, at a depth of 12-13 centimeters (Rojewski, 1983).

The aforementioned is similar to how the largest and sporadically observed in our fauna *Coprimorphus scrutator* (Herbst, 1789) (Ryc. 3C) behaves. Over the recent years, this species has been observed in Skowronno near Pińczów (Bidas, 2004), Tylawa near Dukla, Huta Polańska near Kremowa, Wokowa near Krynica Zdrój (Bidas and Cieślak, 2011), Żubracje near Cisna, and in Przełęcz Wyżna near Wétina (Zięba and Dworakowski, 2008). It inhabits cow dung on the mountain pastures.
These beetles copulate on dung and then each female digs directly underneath the dung 7-8 shallow and vertical tunnels. At the bottom of these tunnels, food is collected for the upcoming offspring and this is also where eggs are laid – always in the lower part of the breeding lump and in compliance with the “one tunnel-one egg” principle. At the initial stage, the larvae feed on food collected in the tunnels and switch to using the dung located above them at a later stage. Prior to the metamorphic stage, the larvae penetrate into the soil and build pupation chamber (Barbero and Palestrini, 1995). The last two dung beetles belong to the Paracoprid group of the species.

Typical Paracoprids (Fig. 4) are domestic species of the following genus: Anoplotrupes Stenstrup, Geotrupes Latreille and Trypocopris Motschulsky.

Dor beetle – Anoplotrupes stercorosus (Scrida, 1791) (Fig. 4A), is the most common and widespread member of the earth-boring dung beetles (Geotrupidae) that inhabits the forests of Poland. It digs 15-35 cm thick tunnels in the soil which are terminated with breeding lumps. Borowski (1960) made a comprehensive investigation into the nourishment spectrum of the dor beetle and presented it to the public. His analysis of the breeding lumps showed that they consist of fragments of leaves, including needles, pieces of bark, and rotting moss. They include no fragments of mushroom fruitbodies or rotten wood. The total amount of the mold buried by beetles of this species is about 1,400 kg per hectare. The most attractive food for the imago dor beetle is dung of large animals as well as decomposed mushroom fruitbodies. Plewińska (2007) points out that the dung beetles fancy the contribution of this dung to the beetle’s diet. Therefore, the high level of attractiveness of rodent dung for the mushroom fruitbodies. Plewińska (2007) points out to the beetles of this species are sometimes found under the carrion poor, old bones! Sensing such an interesting riddle under beating down, the hands and legs become numb. Oh, my poor, old bones! Sensing such an interesting riddle under the ground and yet not being able to dig!”

Another representative of the minotaur beetle – Trypaea typhoeus (Linnaeus, 1758) (Fig. 4C) digs in the ground tunnels that are up to 100-150 cm deep (Brussaard, 1983). The nest of this species was once described by Fabre (1948), “This time, it is no longer the chamber of the scarab, homed dung beetle, or other, which is easy to dug out with the help of a pocket hoe, but a shaft the bottom of which can only be reached by digging for a few hours with a solid shovel. For this work, with the sun still beating down, the hands and legs become numb. Oh, my poor, old bones! Sensing such an interesting riddle under the ground and yet not being able to dig!”

According to Teichert (1959), 7 pairs of the Geotrupes spiniger species (Marsham, 1802) (Fig. 4B) can bury over 12.6 kg of fresh manure during nestling. The mass of the dung buried by a single specimen exceeds by 560 times the mass of the beetle itself (Rojewski, 1980).

The minotaur beetle inhabits moorlands and pine forests on sandy soils where they feed on the excrements of rabbits, deer, roe, and sheep, more seldom of cows and horses (Burański, 1976a). The females dig in the ground, directly under the dung, a few centimeter-long tunnels that end with hatching chambers, where – together with the males – they store food for their offspring (Myrcha, 1973). According to Rommel (1967), the males of this species transport the dung to the entrance of the tunnel, and the females take it into the hatching chamber. At the next stage, the females use the dung (previously collected in the chamber) to sculpt it into 4-8 pear-shaped breeding lumps and lay single eggs in their upper section. The females, and sometimes also the males, remain in the hatching chambers to take care of their offspring. They protect the breeding lumps filled with larvae and pupae and leave the nests with adult offspring (Myrcha, 1973; Mašán and Halliday, 2009).

In Poland, a large group of the Paracoprid species is represented by Onthophagus genus. Quite a number of directly under the dung or in their direct vicinity. Males and females work together while digging nests and transporting faeces. The females dig a tunnel and the males remove the excavated load of earth. The males put the faeces into the burrows where they initially grind it. In a sausage-like shaped hatching chamber, the females transform the faeces into a breeding lump about the size of a finger. An egg is laid in the soil under the breeding lump (Fabre, 1948). In laboratory conditions, the males first picked up the faeces located within a radius of 45 cm of the burrow entrance and then the faeces located at a greater distance. In the latter case, however, they often decided to dig a new entrance to the nest, and when the distance exceeded one meter, they usually left the nest and built new ones located closer to the faeces (Brussaard, 1983; Brussaard and Visser, 1987).

Copris lunaris (Linnaeus, 1758) (Fig. 4D), which belongs to the scarab dung beetles, is a widespread species in our country. It likes to inhabit cattle and horse dung on sunlit pastures, sandy and loamy soils (Steinbach, 1976a). The females dig in the ground, directly under the dung, a few centimeter-long tunnels that end with hatching chambers, where – together with the males – they store food for their offspring (Myrcha, 1973). According to Rommel (1967), the males of this species transport the dung to the entrance of the tunnel, and the females take it into the hatching chamber. At the next stage, the females use the dung (previously collected in the chamber) to sculpt it into 4-8 pear-shaped breeding lumps and lay single eggs in their upper section. The females, and sometimes also the males, remain in the hatching chambers to take care of their offspring. They protect the breeding lumps filled with larvae and pupae and leave the nests with adult offspring (Myrcha, 1973; Mašán and Halliday, 2009).
these species are known for their sexual dimorphism. Males tend to have horn-like projections or even antlers. According to Fabre (1948), “No bull specimen typical for Swiss pastures has horns so exquisite and so beautifully curved” as the bull-headed dung beetle – *Onthophagus taurus* (Schreber, 1759) (Fig. 4A). It inhabits open sandy and limestone lands of xerothermic nature and the sunlit edges of forests (Burakowski, Mroczkowski and Stefańska, 1983). In our country, it is widespread in the Silesia (Stebnicka, 1976a). According to Hildt (1896) this particular species, “[...] inhabits every type of dung. They form balls about the size of a beans and then lay eggs in them. If they find the ground unsuitable, they roll the ball to a more appropriate location, where they bury it and themselves deep in the ground. Although, these beetles live in groups, each pair manufactures its own ball. [...] They are totally absent in the Warsaw area. They appear only in the Radom Governorate and, more often, in the Hrubieszów district.”

*Sisyphus schaefferi* (Linnaeus, 1758) (Fig. 4B), is the second species of the Telecoprid group, was found over a century ago in Pulawy and Janowice of the Lublin Upland. It inhabits steppe areas, dry pastures, and mild sunlit slopes. Adults feed on cattle dung, particularly that of the sheep. The food is collected in the form of pear-shaped balls stored in underground chambers which is where these beetles lay their eggs. However, they fail to care for their offspring (Burakowski, Mroczkowski and Stefańska, 1983). According to Hildt (1896), “It stays in fat manure and quite willingly in human excrements. It lives in pairs. Each pair forms little balls of the dung, buries them in the ground and lays eggs in them. They move in a clumsy, goat-like manner and with difficulty on even ground. [...] In our country, they are observed mostly in the southern part of the Lublin Governorate; they are pretty popular in the Galicia. [...] It is absent in the Warsaw area”.

Sacred scarab beetle – *Scarabaeus sacer* (Linnaeus, 1758) (Fig. 5C), is the third species of the Telecoprid group reported in our country several years ago. J. A. Wolf’s collection included a scarab specimen from the Cracow area. We know this from Karol Herman de Perlhées’ notes archived in the Institute of Systematics and Evolution of Animals of the Polish Academy of Sciences (PAN). However, the specimen itself was destroyed during a fire at the University of Kiev (Śliwa, 2003). At present day, the closest sites of the scarabs are located in Hungary (*Scarabaeus typhon* (Fischer von Waldheim, 1823) and *S. pius* (Illiger, 1803) and Ukraine (*S. sacer* and *S. typhon*). In the 18th, 19th and early 20th centuries, the scarabs were also found within the areas of the present-day Austria, the Czech Republic, and Slovakia. In 1961, the *S. typhon* scarab was found in Kováčov on the Danube in the southern part of Slovakia. According to Hildt (1896), “Insects of this genus are not at all present in our region [...] They are sometimes observed in the Podolia and Kherson Governorates [...] two specimens [...] I found near the Rozdzielna railroad station”. The city of Rozdzielna is currently located within the territory of Ukraine, approximately 60 km from
Dung beetles and their role in the nature

EDUKACJA BIOLOGICZNA I ŚRODOWISKOWA 1/2018

Odessa. The scarabs’ natural habitat is fresh dung lying on the routes of the livestock (sheep, cows, and horses). The adult scarabs use their front section of the head and the legs (with distinctive tooth–like projections on the outer edges) to cut down portions of the dung.

On midsize pastures located near Cuglieri in Sardinia, the authors observed a swarm of *Ateuchetus laticollis* (Linnaeus, 1767) (Fig. 6) and the method the scarabs used to handle the dung. In the afternoon of a sunny May day, hundreds of specimens could be admired in the air and on the ground. One of the observed scarabs of this species cut the dung off and tentatively modeled a ball in 4 minutes. This beetle was vigorously moving his head and legs while turning around his own axis. After making suitably deep cuts, the pre-formed ball was separated from the rest of the dung under the weight of the beetle sitting on it. Next, the scarab embraced the ball with his hind legs and, standing still in vertical position with his head down, began to push his forelegs away from the ground, setting the ball in motion. Rolling a portion of fresh dung cut by the beetle caused its shape to become more spherical with its diameter reaching approximately 2 cm. Larger scarabs (3-5 cm in diameter) are able to roll balls much larger in size (3-5 cm) and the largest specimens are skilled enough to manufacture a ball as large as 6 cm. Quite frequently, the size of a ball exceeds that of the beetle itself (Byk and Piętka, 2011), and it is 10 to 20 times heavier (Doube and Dalton, 2003). The modeled ball of manure can be rolled by a scarab, or a pair of scarabs, even at a distance of several dozens of meters.

It is not uncommon that scarabs of the same species fight for the modeled ball. It happens that an individual who has put a lot of effort into modeling the ball is chased away by a stronger opponent. Sometimes, the specimens of two species, differing largely in size, compete for the ball. In Sardinia, the authors observed an
The colder it gets, the lower the number of species

As we advance towards the south of Europe, the number of individuals of coprophagic species belonging to the Scarabaeidae family increases amongst the representatives of the Scarabaeoidea superfamily, both in open and forested areas. They are dominated by species of the following genus: Onthophagus, Gymnopleurus, Sisyphus and Scarabaeus (Balthasar, 1964). Concurrently, the number of individuals of the Geotrupidae species tends to be reduced (Byk, 2012). According to Hortal et al. (2011), no low-temperature adaptation mechanisms were developed amongst the representatives of the Onitini and Scarabaeini tribes that would allow new areas to colonized or the species to survive in northern Europe. Located in northeastern Italy, the La Mandria Park – a patchwork of the open and forested areas – as much as 94% of the coprophagous Scarabaeoidea were the Scarabaeidae (including 32.5% of the Aphodiinae specimens) and the Geotrupidae specimens constituted as little as 6% of the group (Barbero et al., 1999).

Across the pastures of Poland, the core of the coprophagous Scarabaeoidea groupings consist of the Scarabaeidae, but the Aphodiinae subfamily, i.e. the Acrosus rufipes (Linnaeus, 1758), Agrilinus ater, Aphodius pedellus (De Geer, 1774), Bodilopis rufa (Moll, 1872), Chilothorax distinctus (Müller, 1776), Colobopterus erraticus, Eysmus pusillus (Herbst, 1789), Eupeirus subterraneus (Linnaeus, 1758), Melinopterus prodromus (Brahm, 1790), M. sphacelatus (Panzer, 1798), and Othophorus haemorrhoidalis (Linnaeus, 1758) (Breymeyer, 1974; Stebnicka, 1976b; Bunalski, 1996a, b; Zuk, 2005; Görz, 2007). The core of the coprophagous Scarabaeoidea groupings in the forests of Poland are made by two species of the Geotrupidae – the dor beetle (Anoplotrupes stercorosus) and the spring dor beetle (Trypocoris vernalis). The core is sometimes supplemented by the Acrosus depressus (Kugelann, 1792), A. rufipes, Aphodius pedellus, Chilothorax distinctus, Euordalus coenosus (Panzer, 1798), and Planolinus fasciatus (Olivier, 1789) (Szyżko, 1983; Szwalko, 1995; Byk, 2011, 2012; Byk and Wegrzynowicz, 2015; Kamiński, Byk and Tykarski, 2015). The dor beetle plays a particularly important role in our domestic forests. It is a frequent inhabitant of the pine forests growing on the wooded areas and is observed in much larger numbers in the forests growing on the former farmlands. By inhabiting the forest stands growing on the former farmlands, by digging tunnels and burying wild animal dung and rotten leaves, it changes the properties of the post-agricultural soil hollowing and speeds up the forest-type land forming process (Byk, 2004; Byk and Semkiw, 2010). The above considerations show that open areas (meadows, pastures, fallows) as well as wooded areas are inhabited by groups of dung beetles of different structure (composition and quantity of the species).

First come, first served

A large quantity of dung beetles forces individual species to compete for food of an ephemeral nature. It appears suddenly and disappears within a short time or is unsuitable to inhabit. The result of this competition includes, without limitation, the previously presented different strategies the Endocoprids, Paracoprids, and Telecoprids apply to deal with dung. It is also extremely important to have the time necessary to reach the dung. The “first come, first served” strategy has been adopted by a large group of Telecoprids. Quite often, the Telecoprids find dung within a few minutes after its appearance as only the fresh dung is suitable for modeling a ball. To do this, the scarabs sometimes follow directly a herd of sheep. Their rush was described by Fabre (1948), “Who is that stepping so hastily, as if afraid of being late? Long legs are moving quickly and awkwardly as if set in motion by an invisible mechanism hidden in the insect’s stomach; little red horns distributed in a fan-like manner – a sign of restless lust. Here it comes – it’s already arrived running over a few fellow revelers. It is Scarabaeus sacer, the sacred scarab beetle”. The Paracoprids and Endocoprids usually come to
Dung beetles and their role in the nature

**What’s in it for us?**

The dung beetles (coprophagous *Scarabaeoidea*) play an extremely significant role in natural ecosystems, especially in the circulation of elements and secondary dispersal of seeds (Nichols et al. 2008). According to Rojewski (1980), Bunalíski (1995) and Görz (1999), the role of the coprophages in meadow ecosystems consists in:

- Preventing the occurrence of the “dung pollution” phenomenon by reducing the mass of animal dung;
- Stimulating the dung mineralization process by burying and grinding it;
- Aerating and improving the structure of the soil by digging tunnels at various depths;
- Improving the amount humus in the soil by burying the dung;
- Reducing the number of coprobiontic dipterans (including the bloodsucking species);
- Reducing the quantity of parasitic nematodes by crushing their eggs.

According to Rembiáłkowska (1980), the role of the pasture and forest species of the dung beetles is similar and consists in grinding and mixing of the soil with faeces of different species of mammals. A slightly different role is played by the dor beetle, which enriches the deeper, mineral layers of the soil with organic matter by burying the forest litter in the form of breeding lumps. This is of special importance for meager forest habitats where saprophagous macrofauna, e.g. earthworms, is rarely observed. The commonness and the role of the dung beetles are best evidenced by numbers:

- 10 specimens of the minotaur beetle (*Typhaeus typhoeus*) species can bury around 400 balls of rabbit dung in 25 days (Spaney, 1910);
- On a pasture located near Berlin, there were 825 specimens of the aphodine dung beetles, 38 specimens of the earth-boring dung beetles and 70 specimens of the *Onthophagus* genus dwelling in a portion of sheep dung, and 92 specimens of the *Geotrupes stercorarius* (Linnaeus, 1758) (Burmeister, 1936) species were found in a portion of horse dung;
- European species of the earth-boring dung beetles during the nest building period bury approximately from 0.2 to 0.7 kg of dung (Teichert, 1959);
- In Algeria, some 450 specimens of the *Gymnopleurus* genus and 190 other dung beetles in a single, Ø35 cm portion of cow dung, and 31 scarabs in another portion of dung (Balthasar, 1963) were observed;
- In Algeria, 80 beetles of the *Thorectes* *Mulsant* genus and *Steropeygae* A. *Costa* subgenus were observed on each square meter of a cornfield with freshly dispersed manure; each of these beetles buried 20 grams of dung; therefore, 800,000 specimens buried almost 16 tons of dung per hectare (Balthasar, 1963);
- In the Johannesburg area, there were usually 400 specimens of the *Aphodinae* subfamily, 50 species of the *Onthophagus* genus, 50 specimens of the *Oniticellus* genus, 40 specimens of the *Onitis* genus, 2 specimens of the *Copris* genus, and 5 species of the *Sisyphus* genus (Gillard, 1967);
- Parasitic flies of the *Haematobia irritans* (Linnaeus, 1758) species cause approximately $730 million in losses to cattle farming (Drummond et al., 1981), while the dung beetles can reduce the number of these flies by as much as 95% (Bornemissza, 1970, 1976);
- Under laboratory conditions, a pair of specimens of the *Onitis* genus can bury 0.7 kg of dung within 10 days’ time (Doubé and Dalton, 2003);
It is estimated that the dung beetles allow the US farmers to save $380 million a year (Losey and Vaughan, 2006).

The key evidence of the tremendous importance of the dung beetles for nature is the role they played in Australia. In 1778, the Europeans settled in Australia and brought with them many species of crops and livestock. As cattle farming developed across the entire country, along came unprecedented pollution of pastures with dung (the so-called dung pollution) as well as the mass emergence of flies developing in the dung. Unfortunately, it also included the parasitic and bloodsucking species. Due to dung pollution, the area of pastures available to animals was rapidly decreasing. Under the country’s climatic conditions, the dung quickly dried up and turned into “crust” that remained in place for several years. For this reason, the further development of sheep, cows, and horses has been questioned. The main reason for this was the lack of native coprophages that could grow in the cattle dung. Therefore, further development of sheep, cow and horse farming became pretty questionable. The main reason of this situation was the lack of domestic coprophages that could develop in animal dung. Domestic dung beetles have evolved together with the marsupials and learned to use their faeces (Waterhouse, 1974; Bornemissza, 1976). Domestic dung beetles work of Ludwik Fryderyk Hildt and by Jean-Henri Casimir Fabre’s works devoted to the life of insects.

From among the insects that defend us against dangerous waste, shamelessly decaying in the rays of sunshine, dung beetles deserve most of the attention (Fabre, 1948).
